The present invention demonstrates the synthesis of a new pyrazole-containing monomer by means of an easily implemented two-step process. This monomer can be electropolymerized to yield a stable n-doping polymer that may easily be electrochemically characterized. It is demonstrated that the electrochemical behavior of the polymer films produced is dependent upon the conditions applied during electrodeposition. Films deposited by cycling only at relatively positive potentials (0 to 2000 mV) show less intense n-doping responses than those films obtained by scanning the applied potential throughout a wider range (~2000 mV to 2000 mV).

BIS(THIENYL)ISOPYRAZOLES AND PROCESS FOR PREPARING AND METHOD FOR USING BIS(THIENYL)ISOPYRAZOLES

This application is a continuation of U.S. patent application Ser. No. 11/645,257, filed Nov. 25, 2006, pending.

STATEMENT REGARDING FEDERALLY SPONSORED RESEARCH OR DEVELOPMENT

The invention described herein may be manufactured and used by or for the government of the United States of America for governmental purposes without the payment of any royalties thereon or therefor.

FIELD OF THE INVENTION

The present invention relates to processes for preparing bis(thienyl)isopyrazoles via condensation and to methods for using bis(thienyl)isopyrazoles.

BACKGROUND OF THE INVENTION

Electroactive polymers can generally be switched between two or more stable oxidation states, giving rise to changes in properties including conductivity, color, volume, and transmissivity. [G. Inzelt, M. Pineri, J. W. Schultzze, and M. A. Vorontysnev, Electrochem. Acta, 45, 2403 (2000)]. Electroactive polymers which have been oxidized from a neutral state are said to be p-doped, by analogy to semiconductor terminology. Likewise, polymers that have been reduced from a neutral state are said to be n-doped. Owing to the inherent stability of carboxylations, p-dopable materials are quite well known and have been thoroughly documented. [G. Inzelt, M. Pineri, J. W. Schultzze, and M. A. Vorontysnev, Electrochem. Acta, 45, 2403 (2000); J. Jagur-Grodzinski, Polym. Adv. Tech., 13, 615 (2002); and, J. W. Schultzze and H. Karabulut, Electrochim. Acta, 50 1739 (2005)]. However, stable n-doped polymers have heretofore been unreported. [D. M. de Leeuw, M. M. J. Simenon, A. R. Brown, and R. E. F. Einerhand, Synth. Met., 87, 53 (1997); K. Willbourn and R. W. Murray, Macromolecules, 21, 89 (1988); and, M. Quinto, S. A. Jenekhe, and A. J. Bard, Chem. Mater. 13, 2824 (2001)]. Such n-doped polymers would be desirable for the same reasons that p-doped polymers have been desired and prepared, as well as for use in applications such as batteries and supercapacitors, for example. [A. Rudge, J. Davey, I. Raitstock, S. Gottesfeld, and J. P. Ferraris, J. Power Sources, 47, 89 (1994)]. The instability of n-doping conjugated polymers is most likely due to the highly reactive nature of carbocations. [D. M. de Leeuw, M. M. J. Simenon, A. R. Brown, and R. E. F. Einerhand, Synth. Met., 87, 53 (1997)].

One approach being explored to obtain stable n-doping polymers is the synthesis of donor-acceptor materials. [A. Berlin, G. Zotti, S. Zecchin, G. Schiavon, B. Vercelli, and A. Zanelli, Chem. Mater., 16, 3667 (2004); D. J. Irvin, C. J. DuBois, and J. R. Reynolds, Chem. Comm., 2121 (1999); P. J. Skabara, I. M. Serebryakov, I. F. Perepichka, N. S. Saricifci, H. Neugebauer, and A. Cravino, Macromolecules, 34, 2232 (2001); and, H.-F. Lu, H. S. O. Chan, and S.-C. Ng, Macromolecules, 36, 1543 (2003)]. In a donor-acceptor type of system, the polymer HOMO (highest occupied molecular orbital) is energetically similar to the relatively high-energy HOMO of the donor material, while the polymer LUMO (lowest unoccupied molecular orbital) is energetically similar to the relatively low-energy LUMO of the acceptor. This type of electronic architecture leads to a small HOMO-LUMO gap in the polymers and consequently to a low-lying polymer LUMO suitable for accepting charge.

The electron-poor functionality of the acceptor groups can be obtained in at least two ways. In the most common approach, electron-withdrawing substituents such as nitro- or fluoro-groups, for example, are incorporated pendant to the main chain of the polymer. [D. J. Irvin, C. J. DuBois, and J. R. Reynolds, Chem Comm. 2121 (1999); and, P. J. Skabara, I. M. Serebryakov, I. F. Perepichka, N. S. Saricifci, H. Neugebauer, and A. Cravino, Macromolecules, 34, 2232 (2001)]. While this method can yield electron-deficient monomer units and ultimately electron-deficient polymers, it is likely that the substituents act as charge traps, hindering electron mobility. Electron mobility might be improved, without the aid of pendant groups, by incorporation of functional groups that are themselves intrinsically electron-deficient such as the high nitrogen heterocycles. Typically, as the number of imine-type nitrogens replacing carbon in a given aromatic ring increases, so too does that ring's electron affinity. [G. Brooks and A. Tol, Synth. Met., 101, 516 (1999)]. Empirically, the higher the electron affinity of the polymer, the more stable the polymer will be in the n-doped state. [A. P. Kulkarni, C. J. Tonzola, A. Babal, and S. A. Jenekhe, Chem. Mater. 16, 4556, (2004)]. Incorporation of these high nitrogen heterocycles into conjugated polymers should result in n-dopable polymers with good electron mobility. Limited research into this type of donor-acceptor polymer has been conducted by others. [A. Berlin, G. Zotti, S. Zecchin, G. Schiavon, B. Vercelli, and A. Zanelli, Chem. Mater., 16, 3667 (2004); and, H.-F. Lu, H. S. O. Chan, and S.-C. Ng, Macromolecules, 36, 1543 (2003)]. The present invention discloses a new stable n-doping donor-acceptor polymer.

SUMMARY OF THE INVENTION

The present invention demonstrates a new stable n-doping donor-acceptor polymer. Thiophene units have been chosen as the electron-rich portion of the polymer, while the isopyrazole ring has been chosen as the electron deficient portion. The isopyrazole group provides high electron affinity and ease of functionalization. [G. Brooks and A. Tol, Synth. Met., 101, 516 (1999)].

BRIEF DESCRIPTION OF THE DRAWINGS

FIGS. 1a-1e are Voltammograms generated by repeated cycling of applied potential at 30 mV/s during electropolymerization of DTDPy.

FIGS. 2a-2e is a diagram of redox cycling of poly(DTDPy) showing prominent p-doping responses and faint n-doping signals.

FIGS. 3a-3e is a diagram of electrodeposition of poly(DTDPy) at 30 mV/s with an expanded potential scan range (2000 to -2000 mV) to include n-doping potentials.

FIGS. 4a-4e is a diagram of redox cycling of poly(DTDPy) film produced with an expanded potential scan.

FIGS. 5a-5e are Voltammograms of poly(DTDPy) films indicating that oxidation with an onset of 1200 and reduction centered at 200 mV are coupled.

DETAILED DESCRIPTION OF THE INVENTION

A novel donor-acceptor polymer based on thiophene and isopyrazole has been prepared for use in n-doping applications. Non-polymerizable monomer radical cations appear to be the predominant oxidation product, resulting in a need for...
extended cycling to produce adequate quantities of polymer for characterization. Cycling to reductive potentials during oxidative polymerization was necessary to produce a polymer film capable of n-doping, likely resulting from a need to establish pathways for cation migration. The electrochemical behavior of the polymer films produced is strongly dependent upon the conditions applied during electrodeposition. The neutral polymer undergoes oxidation to the p-doped form at ca. 2000 mV vs. Ag/Ag⁺ and reduces back to neutral at ca. 0 mV. Conversion of the neutral polymer to its n-doped form involves reductions at ~700 and ~1300 mV, with re-oxidation at ~800 and ~200 mV to return to the neutral form of the polymer.

As the electron-rich portion of the polymer we have chosen thiophene units, while we have chosen the isopyrazole ring as the electron deficient portion. The isopyrazole group provides high electron affinity and ease of functionalization. [G. Brocks and A. Tol, Synth. Met., 101, 516 (1999)].

**EXPERIMENTAL**

Dimethyl malonyl chloride, n-butylithium (2.5 M in hexanes), zinc chloride (1.0 M in diethyl ether), 2-bromothiophene, and palladium (II) chloride were purchased from Aldrich and used as received. Tetramethyltriphenylphosphine palladium (0), also commonly written Pd(PPh₃)₄, was synthesized by reduction of PdCl₂ with hydrazine in the presence of triphenylphosphine, also commonly written PPh₃.

All electrochemical experiments were performed in a nitrogen atmosphere drybox using a PARSTAT model 2237 potentiostat. Acetonitrile was dried by distillation from calcium hydride. Propylene carbonate was dried by distillation from calcium oxide. Tetramethylammonium tetrafluoroborate (TMABF₄) was recrystallized twice from methanol/water. The electrolyte was then dried in a vacuum oven at 110°C for twenty-four hours before use. Electrolyzermerizations were conducted with a 10 mM solution of monomer in 100 mM TMABF₄/acetonitrile. The working, auxiliary, and reference electrodes were a platinum button (diameter=1.6 mm; area=0.02 cm²), a platinum flag, and a non-aqueous Ag/Ag⁺ reference electrode, respectively. The potential of the Ag/Ag⁺ reference electrode was calibrated using the ferrocene/ferrocenium couple. The reduction potential of the couple was found to be 97 mV vs. the reference electrode. All potentials reported herein are relative to the Ag/Ag⁺ reference electrode. Cycling of the polymer films was accomplished using monomer-free 100 mM TMABF₄ in propylene carbonate as the electrolyte system.

**Example 1**

**Synthesis of 1,3-Dithien-2-yl-1,2,2-dimethylpropane-1,3-dione (DMDTPy)**

2-bromothiophene (12.4 mL, 32.0 mmol) was added to 500 mL dry diethyl ether. Then n-butyl lithium (2.5 M in hexanes, 508 mL, 127.2 mmol) was added and the mixture was stirred for sixty minutes. After this time, ZnCl₂ (1.0 M in ether, 127.2 mL, 127.2 mmol) was added slowly, giving a white precipitate. Next, the reaction mixture was allowed to slowly warm to room temperature and was then refluxed for four hours. Following the reflux period, the reaction mixture was cooled to room temperature and Pd(PPh₃)₄ (1.85 g, 1.6 mmol) was added followed by the slow addition of dimethyl malonyl chloride (2.0 mL, 15.1 mmol). After completion of the additions, the reaction mixture was brought to reflux and stirred overnight.

After this time, the reaction mixture was poured into 500 mL saturated aqueous sodium bicarbonate. The two-phase mixture was filtered and separated. The organic phase was washed with brine and dried over sodium sulfate. The solvent was removed by rotary evaporation to give a pale orange solid. This solid was dissolved in a minimal amount of acetone and passed through a short plug of silica gel using hexanes as the eluent. Upon removal of the solvent, a pale yellow solid was obtained. This material was recrystallized from hexanes to give pale yellow needles. Yield 3.7 g, 23%. Mp: 159-162°C. ¹H NMR (CDCl₃) δ 7.54 (m, 4H), 6.99 (t, 2H, J=5.0, 4.0 Hz), 1.69 (s, 6H). IR (KBr pellet, cm⁻¹): 3114.4, 3099.0, 2994.1, 2932.5, 1663.3, 1563.2, 1512.9, 1461.1, 1408.0, 1352.6, 1268.8, 1254.0, 1241.7, 1172.6, 1054.3, 965.5, 903.9, 852.1, 825.0, 748.5, 726.3.

**Example 2**

**Synthesis of 3,5-Dithien-2-yl-4,4-dimethylpyrazole (DMDTPy)**

DMDTPy (1.25 g, 4.7 mmol) and anhydrous hydrazine (1.5 mL, 47 mmol) were combined in 100 mL toluene. The resulting solution was then refluxed for eighteen hours. After this time, the solvent was removed by rotary evaporation and the bright orange solid remaining was collected and dried in vacuo. Yield 1.21 g, 98%. Mp: 153-156°C. ¹H NMR (CDCl₃) δ 7.65 (dd, 2H, J=3.8, 1.0 Hz), 7.52 (dd, 2H, J=5.0, 1.0 Hz), 7.17 (dd, J=5.1, 3.8 Hz), 1.70 (s, 6H). IR (KBr pellet, cm⁻¹): 3095.9, 2988.0, 2972.6, 2929.4, 2861.5, 1538.2, 1492.0, 1455.0, 1430.3, 1226.7, 1057.1, 850.4, 835.0, 720.8, 699.3.

**Discussion of Examples and Results**

Synthesis of the monomer 3,5-Dithien-2-yl-4,4-dimethylpyrazole (DTDMPy) was accomplished using a novel two-step process (Diagram 1). The first step of the process entails coupling a thienylzinc reagent to dimethyl malonil chloride using a palladium (0) catalyst. The poor ether solubility of the thienylzinc reagent likely contributed heavily to the low yields (23%) attained. The target was easily separated from side products by chromatography and further purified by recrystallization from hexanes. The thienylzinc reagent was more soluble in THF than in ether, but the material isolated after the reaction in THF was a complex mixture that could not be readily separated. Infrared spectroscopy of the product showed a sharp, prominent absorbance at 1636 cm⁻¹, indicating that conjugated carbonyl groups were present; ¹H NMR of the product was consistent with the proposed structure.

The second step of the process, a ring-closing reaction with excess hydrazine to provide the pyrazole ring, was accomplished in nearly quantitative yield. This result indicates that the ring-closing step is much more kinetically favorable than is the addition of a second hydrazine to the dione. Infrared spectroscopy of this product showed no trace of the carbonyl vibration observed with the precursor, indicating that the conversion to pyrazole was complete. It will be understood by one skilled in the art that this general reaction scheme may be applied to other ring systems besides thiophene to give a wide array of diarylpyrazole derivatives, including those that are more electron-deficient than DTDMPy.
This general reaction scheme has been successfully applied to produce other diarylpyrazole derivatives including those substituted at the 4-position of the pyrazole ring with alkyl chains, polyether, or fluorine as shown in Diagrams 2-4, as well as to produce diarylpyrazole derivatives having functionalized thiophenes as shown in Diagram 5, where R may be a substituted or unsubstituted alkyl, aryl, or oligoether groups. Such substitutions provide a means to manipulate the electronic and/or solubility properties of the monomer.
A vital consideration in monomer design is the substitution pattern of the pyrazole ring. In order to produce a monomer suitable for electroactive polymers, it is necessary to quaternize the carbon at the 4-position of the pyrazole ring. An unsubstituted pyrazole in this situation has as its major resonance form a protonated amine as part of the ring (Diagram 6). Such an electronic structure of course serves as a conjugation break. In order to exclude this resonance structure, the carbon at the 4-position must be fully substituted. Dimethyl malonyl chloride, a commercially available building block, was used with the expectation that the methyl groups would provide the correct electronic structure for a fully conjugated polymer. In addition, after electropolymerization, the methyl substituents do not impart much solubility to the polymer. Indeed, the polymer films disclosed herein are insoluble in both acetonitrile and propylene carbonate. This property facilitates electrochemical characterization of the films.

Initial electropolymerizations of DTDMPy were accomplished by cycling the potential applied to a platinum button repeatedly between 0 and 2000 mV versus Ag/Ag⁺ reference. All electrochemical potentials are with respect to this reference. It was necessary to cycle the potential for two hours to produce a film thick enough for electrochemical characterization. This extended cycle time is in contrast to those reported for more electron-rich monomers, such as thiophene derivatives that can be deposited in a relatively shorter time. [G. P. Evans, in *Advances in Electrochemical Science and Engineering*, H. Gerischer and C. W. Tobias, Editors, p. 1, VCH Publishers, Inc., New York, 1990]. With reference to Figs. 1a-1c, voltammograms generated by repeated cycling of applied potential at 30 mV/s during electropolymerization show monomer oxidation onset at about 1200 mV and peak at about 1800 mV together with a slowly increasing current response centered at about 1200 mV. This increasing current response may be attributed to polymer oxidation. Interestingly, there is no discernable corresponding reduction for the polymer. Instead, reductions at more positive potentials are present which are most likely due to monomer reduction. This suggests that a large portion of the monomer is first oxidized and then reduced without coupling to form polymer. Hence, the polymer reduction response is most probably obscured by the more intense monomer reduction current.

The limited coupling occurring upon monomer oxidation may be explained by considering the effect of the pyrazole ring on the resonance forms of the monomer. As is the case with a monomer such as terthiophene, oxidation gives a radical cation. The radical may be located at the 5-position of a terminal thiophene, thus leading ultimately to 2,5-linked polythiophene (Diagram 7). However, if the radical migrates through the terthiophene monomer, it may be located on the 3- or 4-position of one of the thiophene rings. This electronic arrangement leads to the often undesirable irregularly linked polymer chains that are not fully conjugated.
Diagram 7. Oxidation forms of terthiophene and DTDMPy.

By analogy, DTDMPy may be oxidized, giving a radical cation in which the radical is located upon the 5-position of the terminal thiophene. This configuration or form of course gives rise to the desired polymer. On the other hand, the radical may migrate to the 3-position of the pyrazole ring so that the positive charge resides upon the nitrogen at the 1-position of the ring. In this case, the steric hindrance around the radical center most likely prevents any coupling. As the applied potential becomes more negative, the stabilized radical cations are then reduced without coupling. The more prevalent structure or configuration is the resonance form in which the radical is located at the 3-position of the pyrazole ring and the positive charge is found on the nitrogen, given that the monomer redox couple is much more intense in the voltammograms than are the current responses corresponding to the polymer.

With reference to FIGS. 2a-2e, upon cycling of the polymer film in monomer-free 100 mM TMABF₄-propylene carbonate, a redox couple with an onset of about 1500 mV and peak about 1800 mV is readily observed. The rather positive potentials required to oxidize this polymer are most likely a result of the electron-deficient pyrazole units in the polymer backbone. In addition to the p-doping signals, less intense current responses can be observed at more negative potentials, indicating that the polymer is being n-doped. The relative difference in intensity between the p-doping and n-doping regions of the voltammograms are likely a result of the electrodeposition process. As the applied potential is cycled between 0 and 2000 mV to deposit polymer, anions necessarily migrate into the growing polymer film upon oxidation and out of the film upon reneutralization. This process establishes channels for anions to maintain charge balance during post-deposition cycling. Because these anion channels are established during film growth, the process of p-doping proceeds quite well. During polymer reduction, it is likely that cations must be able to freely move into and out of the film. Since the film was not n-doped during deposition, channels for cation migration were not established. Further, because the tetrafluoroanion cations are so much smaller than the tetrafluoroborate anions, the anion channels are inadequate for cation transport.

In order to determine the effects of a broader cycling window, a new film was deposited by cycling the applied potential between ~2000 and 2000 mV. With reference to FIGS. 3a-3e, as observed previously with electrodeposition scans between 0 and 2000 mV, the oxidative region of the voltammograms show oxidations corresponding to the monomer at about 1500 mV and corresponding to the polymer at roughly 1200 mV. In addition, there is a faint n-doping process that can be discerned at roughly ~1200 mV. The voltammograms from this electropolymerization suggest that both anions and cations are moving into and out of the film during the deposition process.

Cycling of the polymer films in monomer-free electrolyte solution yields the following results shown in FIGS. 4a-4e. First, during the initial cycles between 2.0 and ~2.0 V, the material shows very little electroactivity at all. However, the voltammograms change significantly over the course of 50 cycles before eventually stabilizing. Initially, the polymer oxidation onset at 1200 mV is not accompanied by a peak that could be attributed to reduction of the polymer to the neutral state. The polymer oxidation gradually becomes more prominent with extended cycling, and a reductive current response centered at 200 mV gradually develops. At the same time, more prominent current responses at relatively negative potentials gradually become more intense. The negative current responses at ~700 and ~1300 mV are attributable to reduction of the neutral polymer to the n-doped state, while positive current responses at ~800 and ~200 mV are attributable to oxidation of the n-doped polymer to the neutral state. These n-doping processes are much more intense than those obtained from electropolymerization over the 0 to 2000 mV narrow potential window (FIGS. 1a-1e). Ion channels were established during deposition by cycling between the potentials necessary to both oxidize and reduce the polymer, allowing both anions and cations to move freely within the polymer and between the polymer and the electrolyte solution.

The changes in the voltammograms during extended cycling is thought to be a result of trapped counter ions present in the film. It is usually necessary therefore to first condition the polymer films with several potential scans in order to free trapped ions and permit ion migration. However, some ion trapping may occur even after extended cycling. With reference to FIGS. 5a-5e, the reduction observed at about 200 mV is coupled to the polymer oxidation shoulder. An initial potential scan from 800 to 2500 mV shows that the polymer film displays a shoulder on the solvent degradation signal that corresponds to polymer oxidation. This response, however, is not present on successive scans, indicating that.
the polymer has been oxidized and remained in its oxidized state throughout the experiment. Based upon the evidence that the two signals separated by about one volt are in fact coupled, it is inferred that ion-trapping is occurring.

While the present invention has been described in connection with what are currently considered to be the most practical and preferred embodiments, it is to be understood that the invention is not to be limited to the disclosed embodiments, but to the contrary, is intended to cover various modifications, embodiments, and equivalent processes included within the spirit of the invention as may be suggested by the teachings herein, which are set forth in the appended claims, and which scope is to be accorded the broadest interpretation so as to encompass all such modifications, embodiments, and equivalent processes.

The invention claimed is:

1. A stable n-doping conjugated electroactive polymer comprising:
   poly (3,5-dithien-2-yl-4,4-dimethylpyrazole).

2. A compound represented by the Formula (A):}

3. A stable n-doping conjugated electroactive polymer represented by the Formula A:

4. A compound represented by the Formula (A):

where “n” is an integer equal to or greater than 2.
